**Abstract** Poplar plants are cultivated as woody crops, which are often fertilized by addition of ammonium (NH<sub>4</sub><sup>+</sup>) and/or nitrate (NO<sub>3</sub><sup>-</sup>) to improve yields. However, little is known about net NH<sub>4</sub><sup>+</sup>/NO<sub>3</sub><sup>-</sup> fluxes and their relation with H<sup>+</sup> fluxes in poplar roots. In this study, net NH<sub>4</sub><sup>+</sup>/NO<sub>3</sub><sup>-</sup> fluxes in association with H<sup>+</sup> fluxes were measured non-invasively using scanning ion-selective electrode technique in fine roots of *Populus popularis*. Spatial variability of NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup> fluxes was found along root tips of *P. popularis*. The maximal net uptake of NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup> occurred, respectively, at 10 and 15 mm from poplar root tips. Net NH<sub>4</sub><sup>+</sup> uptake was induced by ca. 48 % with provision of NO<sub>3</sub><sup>-</sup> together, but net NO<sub>3</sub><sup>-</sup> uptake was inhibited by ca. 39 % with the presence of NH<sub>4</sub><sup>+</sup> in poplar roots. Furthermore, inactivation of plasma membrane (PM) H<sup>+</sup>-ATPases by orthovanadate markedly

inhibited net NH<sub>4</sub><sup>+</sup>/NO<sub>3</sub><sup>-</sup> uptake and even led to net NH<sub>4</sub><sup>+</sup> release with NO<sub>3</sub><sup>-</sup> co-provision. Linear correlations were observed between net NH<sub>4</sub><sup>+</sup>/NO<sub>3</sub><sup>-</sup> and H<sup>+</sup> fluxes in poplar roots except that no correlation was found between net NH<sub>4</sub><sup>+</sup> and H<sup>+</sup> fluxes in roots exposed to NH<sub>4</sub>Cl and 0 mM vanadate. These results indicate that root tips play a key role in NH<sub>4</sub><sup>+</sup>/NO<sub>3</sub><sup>-</sup> uptake and that net NH<sub>4</sub><sup>+</sup>/NO<sub>3</sub><sup>-</sup> fluxes and the interaction of net fluxes of both ions are tightly associated with H<sup>+</sup> fluxes in poplar roots.

## Introduction

Nitrogen (N) is an essential component in proteins, nucleic acids, chlorophylls and many secondary metabolites of plants and therefore required as macronutrient for plant growth. Ammonium (NH<sub>4</sub><sup>+</sup>) and nitrate (NO<sub>3</sub><sup>-</sup>) are two main forms of inorganic N available for plants in soil. Plants can absorb and utilize both ions because root cells possess transport systems such as ammonium and nitrate transporters (Jackson et al. 2008). Although both ions can be utilized by plants, NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup> have different energetic and biochemical characteristics for assimilation, resulting in different net fluxes of both ions and NH<sub>4</sub><sup>+</sup>/NO<sub>3</sub><sup>-</sup> preference by plants (Patterson et al. 2010).

Fluxes of NH<sub>4</sub><sup>+</sup>/NO<sub>3</sub><sup>-</sup> in roots have been investigated in the past few decades. Spatial variability in uptake of NH<sub>4</sub><sup>+</sup>

and  $\text{NO}_3^-$  has been found along the roots in herbaceous and woody plants. The net  $\text{NO}_3^-$  uptake increased from the root apex to the basal regions of maize (*Zea mays* cv. Dekalb) and barley (*Hordeum vulgare* L. cv Prato) roots (Henriksen et al. 1992; Taylor and Bloom 1998), but the opposite pattern was observed in rice (*Oryza sativa* L.) and carob (*Ceratonia siliqua* L. cv. Mulata) roots (Cruz et al. 1995; Colmer and Bloom 1998). The highest  $\text{NO}_3^-$  influx occurred at 20–50 mm from the root tips in non-mycorrhizal roots of *Pinus pinaster* (Plassard et al. 2002). In Douglas fir (*Pseudotsuga menziesii*) and Lodgepole pine (*Pinus contorta*) the maximal net  $\text{NO}_3^-$  uptake appeared at 0–30 and 0–10 mm from the root tips, respectively, while the highest net  $\text{NH}_4^+$  uptake occurred at 5–20 mm and 5 mm, respectively (Hawkins et al. 2008). Additionally, temporal dynamics of net ion fluxes and influences of other ions and environmental factors such as pH in the media on net ion fluxes have been reported for roots of maize, barley, rice, coniferous and *Eucalyptus* species (Henriksen et al. 1992; Colmer and Bloom 1998; Garnett et al. 2001, 2003; Hawkins et al. 2008; Hawkins and Robbins 2010; Sorgona et al. 2011).

The interaction of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  on fluxes of both ions and the underlying physiological mechanisms are yet unclear. For instance, net  $\text{NH}_4^+$  uptake was unaffected in the presence or absence of  $\text{NO}_3^-$ , and vice versa, in roots of Douglas fir and lodgepole pine (Hawkins et al. 2008), but the net uptake of  $\text{NO}_3^-$  was markedly reduced when  $\text{NH}_4^+$  was present simultaneously with  $\text{NO}_3^-$  in non-mycorrhizal roots of *Pinus pinaster* (Gobert and Plassard 2007). For most plants including woody plants, high concentrations of  $\text{NH}_4^+$  are toxic, if supplied as a sole N resource and this toxicity disappears if both ions are provided together, whereas no detrimental effects are found in plants supplied with  $\text{NO}_3^-$  as a sole N fertilizer (Babourina et al. 2007; Ehling et al. 2007). Although the underlying mechanisms of  $\text{NH}_4^+$  toxicity are explored extensively (Patterson et al. 2010), little information is available on fluxes of both ions related to  $\text{NH}_4^+$  toxicity in plant roots.

Fluxes of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  in plant roots are associated with plasma membrane (PM)  $\text{H}^+$ -ATPases which extrude protons from the cytosol to the outside at the expense of ATP (Britto and Kronzucker 2006).  $\text{NH}_4^+$  may enter root cells passively through a potential uniporter system following the electrochemical potential gradient across the plasma membrane, but  $\text{NH}_4^+$  must be actively transported out of root cells with the help of PM  $\text{H}^+$ -ATPases during  $\text{NH}_4^+$  efflux (Britto et al. 2001; Britto and Kronzucker 2006).  $\text{NO}_3^-$  is transported into root cells via  $\text{H}^+$ -coupled symporters with involvement of PM  $\text{H}^+$ -ATPases and may leak back passively into the apoplast as efflux (Miller and Cramer 2004; Britto and Kronzucker 2006). Activities of PM  $\text{H}^+$ -ATPases and the expression of the corresponding

genes are induced in response to  $\text{NO}_3^-$  in roots of maize and citrus plants (Santi et al. 1995; Sorgona et al. 2010, 2011). Thus, PM  $\text{H}^+$ -ATPases play an essential role in re-establishing the membrane potential and in maintaining the  $\text{H}^+$  gradient across the PM during  $\text{NH}_4^+$  and  $\text{NO}_3^-$  fluxes (Palmgren 2001; Palmgren and Nissen 2011). It is therefore important to consider PM  $\text{H}^+$ -ATPases when fluxes of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  are under investigation. To our knowledge, however, PM  $\text{H}^+$ -ATPases were not considered in previous studies dealing with fluxes of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  in plant roots.

*Populus* is a model for studies of woody plant biology with ca. 30–40 species mainly distributed in the temperate regions of the north-hemisphere (Polle and Douglas 2010). This genus contains many species adapted to riparian ecosystems in which the moving water table may bring high amounts of N to the roots due to run off from intensive N-fertilization application in agriculture (Rennenberg et al. 2010). In these riparian ecosystems,  $\text{NH}_4^+$  may become rapidly oxidized to  $\text{NO}_3^-$ , rendering it as a major N source for plant roots (Rennenberg et al. 2010 and references therein). Thus, poplars may have different patterns of  $\text{NH}_4^+/\text{NO}_3^-$  fluxes compared with other herbaceous and woody species which require habitats enriched in reduced N forms such as  $\text{NH}_4^+$ . Moreover, most *Populus* species grow in flooded soils (at least during some period of the year), leading to periods with anoxia or hypoxia which can suppress the activity of PM  $\text{H}^+$ -ATPases via a decrease of oxygen and ATP provision. In this context, it also appears important to study the coupling between the inhibition of PM  $\text{H}^+$ -ATPases and the net fluxes of  $\text{NH}_4^+$  and  $\text{NO}_3^-$ . Due to easy propagation and fast growth characteristics, poplar plantations are widely established in recent years and may play crucial roles in the pulp and paper industry, carbon mitigation and biomass production for biofuels (Luo et al. 2006, 2008; Luo and Polle 2009; Novaes et al. 2009; Studer et al. 2011). Poplar plantations are frequently established on marginal land where N is a constraining factor for maximal growth rates (Novaes et al. 2009; Li et al. 2012).  $\text{NH}_4^+$  and  $\text{NO}_3^-$  as N fertilizers are often added to these plantations to maximize yields. Knowledge of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  fluxes in roots of *Populus* species will lead to improved N fertilizer management practices such as selection of N-forms ( $\text{NH}_4^+$ ,  $\text{NO}_3^-$  or both) for application in plantations. However, to date, net fluxes of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  related to PM  $\text{H}^+$ -ATPases are unknown in roots of *Populus* species.

In this study, we employed scanning ion-selective electrode technique (SIET), a powerful tool to investigate ion fluxes in plant roots (Xu et al. 2006). Net  $\text{NH}_4^+$  and  $\text{NO}_3^-$  fluxes associated with PM  $\text{H}^+$ -ATPases were measured non-invasively by SIET along fine roots of *Populus popularis*, which is a species widely distributed in north

China and often selected for afforestation in nutrient-poor soils in this region. The aims of this study are (1) to examine the spatial patterns of net  $\text{NH}_4^+$  and  $\text{NO}_3^-$  fluxes and to determine the positions from the root tips where the maximal net  $\text{NH}_4^+$  or  $\text{NO}_3^-$  uptake occurs; (2) to monitor net  $\text{NH}_4^+$  or  $\text{NO}_3^-$  fluxes associated with PM  $\text{H}^+$ -ATPases and the interaction of both ions and (3) to find the possible correlations between net  $\text{H}^+$  fluxes and net  $\text{NH}_4^+$  or  $\text{NO}_3^-$  fluxes.

## Materials and methods

### Plant cultivation

Cuttings (ca. 15 cm in length, 2 cm in diameter, one-year-old stem) of *Populus popularis* collected from a tree-breeding program (Cao et al. 2012) were rooted and planted in pots (10 L) filled with sandy soil. Each plant was irrigated daily with 50 mL Long-Ashton (LA) nutrient solution (Dluzniewska et al. 2007). Plants were cultivated for 6 weeks in a glass house (natural light; day/night temperate: 25/20 °C; relative humidity: 75 %). Subsequently, plants with similar height (ca. 60 cm) were selected and the root system for each selected plant was carefully washed by tap water. Washed plants were cultivated in hydroponics with modified LA solution (0.1 mM  $\text{NH}_4\text{NO}_3$ , 0.5 mM KCl, 0.9 mM  $\text{CaCl}_2$ , 0.3 mM  $\text{MgSO}_4$ , 0.6 mM  $\text{KH}_2\text{PO}_4$ , 42  $\mu\text{M}$   $\text{K}_2\text{HPO}_4$ , 10  $\mu\text{M}$  Fe-EDTA, 2  $\mu\text{M}$   $\text{MnSO}_4$ , 10  $\mu\text{M}$   $\text{H}_3\text{BO}_3$ , 7  $\mu\text{M}$   $\text{Na}_2\text{MoO}_4$ , 0.05  $\mu\text{M}$   $\text{CoSO}_4$ , 0.2  $\mu\text{M}$   $\text{ZnSO}_4$  and 0.2  $\mu\text{M}$   $\text{CuSO}_4$ , pH 5.5) for 2 weeks. Finally, plants were N starved for 2 days in modified LA solution without  $\text{NH}_4\text{NO}_3$  prior to flux analysis.

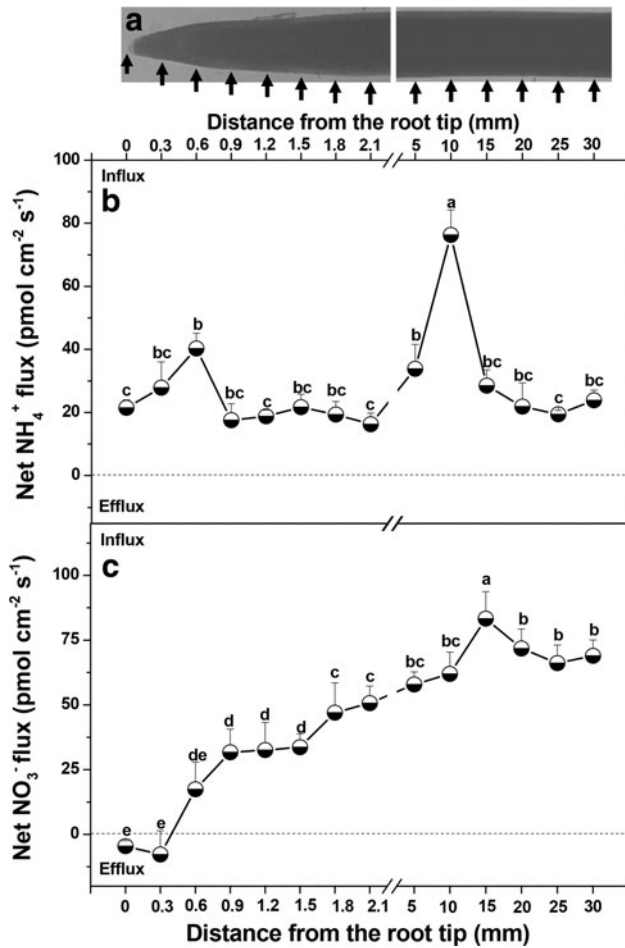

### Measurements of ion fluxes at root surface

To monitor net fluxes of  $\text{NH}_4^+$ ,  $\text{NO}_3^-$  and  $\text{H}^+$  in roots of *P. popularis*, three white fine roots ( $0.31 \pm 0.01$  mm in diameter,  $50.0 \pm 1.1$  mm in length) were selected and excised from the root system (total volume:  $3.56 \pm 0.63$  cm<sup>3</sup>, total surface area:  $861.63 \pm 49.40$  cm<sup>2</sup>, total length:  $274.26 \pm 17.55$  cm, total dry weight:  $1.23 \pm 0.09$  g) of each plant (ca. 9-week-old). The excised roots were immersed in measuring solution. Six plants for  $\text{NH}_4^+$  and another six plants for  $\text{NO}_3^-$  were used for ion flux analyses. The net ion fluxes were measured using scanning ion-selective electrode technique (SIET, system BIO-003A; Younger USA Science and Technology Corp.; Applicable Electronics Inc.; Science Wares Inc., Falmouth, MA, USA) at the company (Xuyue Science and Technology Co., Ltd. Beijing, China). The SIET system and its application in ion flux detection were described in detail

(Xu et al. 2006; Li et al. 2010; He et al. 2011). Briefly, the ion-selective microelectrodes with 2–4  $\mu\text{m}$  apertures were manufactured and silanized [for  $\text{NH}_4^+$  electrode: 100 mM  $\text{NH}_4\text{Cl}$  as backfilling solution, followed by an  $\text{NH}_4^+$ -selective liquid ion-exchange cocktail (#09879, Sigma); for  $\text{NO}_3^-$  electrode: 10 mM  $\text{KNO}_3$  as backfilling solution, followed by a  $\text{NO}_3^-$ -selective liquid ion-exchange cocktail (#7254, Sigma); for  $\text{H}^+$  electrode: 15 mM NaCl and 40 mM  $\text{KH}_2\text{PO}_4$  as backfilling solution, followed by a  $\text{H}^+$ -selective liquid ion exchanger cocktail (#95293, Sigma)]. Prior to the flux measurements, the microelectrodes were calibrated [for  $\text{NH}_4^+$ : 0.05 and 0.5 mM  $\text{NH}_4\text{Cl}$  in addition to other compounds used in the measuring solution (see below); for  $\text{NO}_3^-$ : 0.05 and 0.5 mM  $\text{KNO}_3$  in addition to other compounds used in the measuring solution; for  $\text{H}^+$ : pH 6.0 and pH 5.0 in addition to the compounds used in the measuring solution] and only electrodes were used with Nernstian slopes higher than 55 mV per tenfold concentration difference.

To determine the positions along the root where the maximal ion influxes of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  occur, a preliminary experiment was carried out with an initial measurement at the root tip followed by either 300  $\mu\text{m}$  (in the region of 0–2,100  $\mu\text{m}$ ) or 5 mm (in the region of 5–30 mm) walk steps (Fig. 1a). Gradients of ions ( $\text{NH}_4^+$  and  $\text{NO}_3^-$ ) near to the root surface (ca. 5  $\mu\text{m}$  above the root surface) were measured by moving the ion-selective microelectrode between two positions (with a distance of 30  $\mu\text{m}$ ) in perpendicular direction to the root axis. The recording rate for the ion flux was one reading per 6 s. The ion flux was recorded at each measurement point for 10 min. Acquisition of root images was performed with Magesflux software (version 1.0) attached to the SIET system.

To investigate net  $\text{NH}_4^+$  and  $\text{H}^+$  fluxes associated with PM  $\text{H}^+$ -ATPases and the interference of  $\text{NO}_3^-$  on net  $\text{NH}_4^+$  fluxes, a white fine root was transferred to a Petri dish containing 10 mL of measuring solution (0.1 mM  $\text{NH}_4\text{Cl}$ , 1 mM KCl, 0.1 mM  $\text{CaCl}_2$ , pH 5.5) and equilibrated for 20 min. The equilibrated root was removed to another Petri dish containing fresh measuring solution and used to simultaneously record net  $\text{NH}_4^+$  and  $\text{H}^+$  fluxes for 10 min at the position from the root tip where the maximal net  $\text{NH}_4^+$  uptake was found using  $\text{NH}_4^+$  or  $\text{H}^+$ -selective microelectrodes, respectively. Subsequently, the root was transferred to a Petri dish containing 0.5 mM orthovanadate, which is a specific inhibitor for PM  $\text{H}^+$ -ATPases (Ramos et al. 2009) and incubated for 30 min. Then the root was equilibrated and used to record net  $\text{NH}_4^+$  and  $\text{H}^+$  fluxes as described above. To examine the interference of  $\text{NO}_3^-$  with net  $\text{NH}_4^+$  fluxes, roots were analyzed for net  $\text{NH}_4^+$  fluxes in the measuring solution containing  $\text{NH}_4\text{NO}_3$  instead of  $\text{NH}_4\text{Cl}$  (0.1 mM  $\text{NH}_4\text{NO}_3$ , 1 mM KCl, 0.1 mM  $\text{CaCl}_2$ , pH 5.5) as above.

**Fig. 1** Root tip (a), net NH<sub>4</sub><sup>+</sup> (b) and NO<sub>3</sub><sup>-</sup> (c) fluxes along the root tip of *P. popularis*. Data indicate mean ± SE (*n* = 6). Different letters on the error bars in each panel indicate significant difference among the measured positions. Net influxes correspond to positive values and net effluxes indicate negative values, respectively. The measuring solution contained 1 mM KCl and 0.1 mM CaCl<sub>2</sub>, pH 5.5, to which either 0.1 mM NH<sub>4</sub>Cl for NH<sub>4</sub><sup>+</sup> or 0.1 mM KNO<sub>3</sub> for NO<sub>3</sub><sup>-</sup> flux measurements were added

Similar to the measurements of net fluxes of NH<sub>4</sub><sup>+</sup> and H<sup>+</sup>, net fluxes of NO<sub>3</sub><sup>-</sup> and H<sup>+</sup> were determined at the distance from the root tip where the maximal net NO<sub>3</sub><sup>-</sup> uptake was detected in white fine roots exposed to the measuring solution (1 mM KCl, 0.1 mM CaCl<sub>2</sub>, pH 5.5) containing either 0.1 mM KNO<sub>3</sub> or 0.1 mM NH<sub>4</sub>NO<sub>3</sub> using the ion (NO<sub>3</sub><sup>-</sup> or H<sup>+</sup>) selective microelectrodes. The roots were treated with orthovanadate as described above.

To examine whether there exist correlations between net H<sup>+</sup> fluxes and net NH<sub>4</sub><sup>+</sup> or NO<sub>3</sub><sup>-</sup> fluxes in roots of *P. popularis*, analyses of linear fit were performed using data from net NH<sub>4</sub><sup>+</sup> or NO<sub>3</sub><sup>-</sup> fluxes and net H<sup>+</sup> fluxes before and after orthovanadate treatments.

Measurements of NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup> fluxes in the root xylem

To examine NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup> fluxes in the root xylem, the Petri dish system with two compartments was used as proposed by Sorgona et al. (2011). The measurement procedure for NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup> fluxes in the root xylem was the same as that for ion flux measurements described above. The fine roots (similar size as ion flux measurements by SIET) of *P. popularis* were selected for measurements of NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup> fluxes in the root xylem. The NH<sub>4</sub><sup>+</sup> or NO<sub>3</sub><sup>-</sup> solution collected from one compartment of the Petri dish system was used for NH<sub>4</sub><sup>+</sup> or NO<sub>3</sub><sup>-</sup> quantification spectrophotometrically. NH<sub>4</sub><sup>+</sup> concentration was measured based on the Berthelot reaction (Brautigam et al. 2007). About 100 μL NH<sub>4</sub><sup>+</sup> solution was mixed with 500 μl 1 % (w/v) phenol–0.005 % (w/v) sodium nitroprusside solution. Subsequently, 500 μL 1 % (v/v) sodium hypochlorite–0.5 % (w/v) sodium hydroxide solution was added. The mixture was incubated at 37 °C for 30 min and finally absorption was measured at 620 nm. NO<sub>3</sub><sup>-</sup> concentration was measured at 210 nm as suggested by Sorgona et al. (2011). Finally, the NH<sub>4</sub><sup>+</sup> or NO<sub>3</sub><sup>-</sup> flux in the root xylem was estimated using the NH<sub>4</sub><sup>+</sup> or NO<sub>3</sub><sup>-</sup> amount, the area of root xylem on the cross section and the time which was used for collection of NH<sub>4</sub><sup>+</sup> or NO<sub>3</sub><sup>-</sup> in one compartment of the Petri dish system.

Data processing and statistical analysis

Net ion flux data were calculated and exported with Mageflux software (version 1.0) attached to the SIET system (Xu et al. 2006). For determination of the positions along the root tip with the maximal net NH<sub>4</sub><sup>+</sup> or NO<sub>3</sub><sup>-</sup> influx of the fine root, readings for net ion NH<sub>4</sub><sup>+</sup> or NO<sub>3</sub><sup>-</sup> influxes within 10 min were averaged at each measuring point in each plant. One-way ANOVA was performed using the distance from the root tip as a factor. For analyses of net fluxes of NH<sub>4</sub><sup>+</sup>, NO<sub>3</sub><sup>-</sup> and H<sup>+</sup> at the distance from the root tip with the maximal fluxes, readings were averaged for net ion (NH<sub>4</sub><sup>+</sup>/NO<sub>3</sub><sup>-</sup>/H<sup>+</sup>) fluxes within 10 min in each plant. The effects of vanadate and N source (NH<sub>4</sub>Cl/KNO<sub>3</sub>/NH<sub>4</sub>NO<sub>3</sub>) on net ion fluxes (NH<sub>4</sub><sup>+</sup>/NO<sub>3</sub><sup>-</sup>/H<sup>+</sup>) were analyzed by two-way ANOVAs. All statistical tests were performed with STATGRAPHICS (STN, St. Louis, MO, USA). Data were tested for normality prior to the statistical analysis. Differences between means were considered to be significant when the *P* value of the ANOVA *F*-test was less than 0.05.

## Results

Positions for the maximal net uptake of  $\text{NH}_4^+$  and  $\text{NO}_3^-$

To determine the positions where the maximal net uptake of  $\text{NH}_4^+$  or  $\text{NO}_3^-$  into roots of *P. popularis* occurs, net  $\text{NH}_4^+$  and  $\text{NO}_3^-$  fluxes were monitored along the root tip up to 30 mm from the apex (Fig. 1b, c). Net  $\text{NH}_4^+$  influxes varied dramatically from 16 to 76  $\text{pmol cm}^{-2} \text{s}^{-1}$  along the root tip (Fig. 1b). The maximal net  $\text{NH}_4^+$  uptake was detected at 10 mm from the root tip (Fig. 1b). Net  $\text{NO}_3^-$  fluxes ranged from  $-8$  (efflux) to 83 (influx)  $\text{pmol cm}^{-2} \text{s}^{-1}$  along the root apex (Fig. 1c). At 15 mm from the root tip, net  $\text{NO}_3^-$  flux displayed the maximum influx among the analyzed positions in the root apical region (Fig. 1c).

Net  $\text{NH}_4^+$  and  $\text{H}^+$  fluxes and their correlations

At 10 mm from the root tip of white fine root of *P. popularis* where the maximal net  $\text{NH}_4^+$  uptake was detected, net  $\text{NH}_4^+$  influxes were investigated in detail (Fig. 2a, b, e). At this position, net  $\text{NH}_4^+$  influxes displayed little fluctuation in 10 min (Fig. 2a, b). The mean of net influx of  $\text{NH}_4^+$  in 10 min was ca. 76.3  $\text{pmol cm}^{-2} \text{s}^{-1}$  and the orthovanadate treatment significantly decreased net influx of  $\text{NH}_4^+$  by 52 % in roots exposed to 0.1 mM  $\text{NH}_4\text{Cl}$  (Fig. 2e). Under 0 mM orthovanadate conditions, net influx of  $\text{NH}_4^+$  was stimulated by 48 % in roots exposed to 0.1 mM  $\text{NH}_4\text{NO}_3$  compared with that in roots exposed to 0.1 mM  $\text{NH}_4\text{Cl}$  (Fig. 2e). Under 0.1 mM  $\text{NH}_4\text{NO}_3$  conditions, the orthovanadate treatment markedly decreased net influx of  $\text{NH}_4^+$  and led to net efflux of  $\text{NH}_4^+$  (Fig. 2e).

Accompanying net  $\text{NH}_4^+$  flux measurement, net  $\text{H}^+$  fluxes were also determined (Fig. 2c, d, f). The mean of net efflux of  $\text{H}^+$  in 10 min was  $-6.9 \text{ pmol cm}^{-2} \text{ s}^{-1}$  in roots exposed to 0.1 mM  $\text{NH}_4\text{Cl}$ , and it was significantly decreased and showed a weak net influx after the orthovanadate treatment (Fig. 2f). Under 0 mM orthovanadate conditions, net efflux of  $\text{H}^+$  was stimulated four folds in roots exposed to 0.1 mM  $\text{NH}_4\text{NO}_3$  compared with that in roots exposed to 0.1 mM  $\text{NH}_4\text{Cl}$  (Fig. 2f). Under 0.1 mM  $\text{NH}_4\text{NO}_3$  conditions, 0.5 mM orthovanadate exposure markedly decreased net efflux of  $\text{H}^+$  and displayed net influx of  $\text{H}^+$  compared with 0 mM orthovanadate (Fig. 2f).

The correlations were analyzed between net  $\text{NH}_4^+$  fluxes and net  $\text{H}^+$  fluxes in fine roots exposed to 0.1 mM  $\text{NH}_4\text{Cl}/\text{NH}_4\text{NO}_3$  in the presence or absence of 0.5 mM orthovanadate (Fig. 3a–d). No correlation was found between net  $\text{NH}_4^+$  influxes and net  $\text{H}^+$  effluxes in the monitored period of time in roots exposed to 0.1 mM  $\text{NH}_4\text{Cl}$  (Fig. 3a). After inhibition of PM  $\text{H}^+$ -ATPases, net

$\text{H}^+$  uptake decreased when net  $\text{NH}_4^+$  influxes increased in the measuring period for roots in 0.1 mM  $\text{NH}_4\text{Cl}$  (Fig. 3b). Net  $\text{H}^+$  effluxes increased with net  $\text{NH}_4^+$  influxes when roots were exposed to 0.1 mM  $\text{NH}_4\text{NO}_3$  (Fig. 3c). After 0.5 mM orthovanadate treatment, net  $\text{H}^+$  influxes increased with net  $\text{NH}_4^+$  effluxes (Fig. 3d).

Net  $\text{NO}_3^-$  and  $\text{H}^+$  fluxes and their correlations

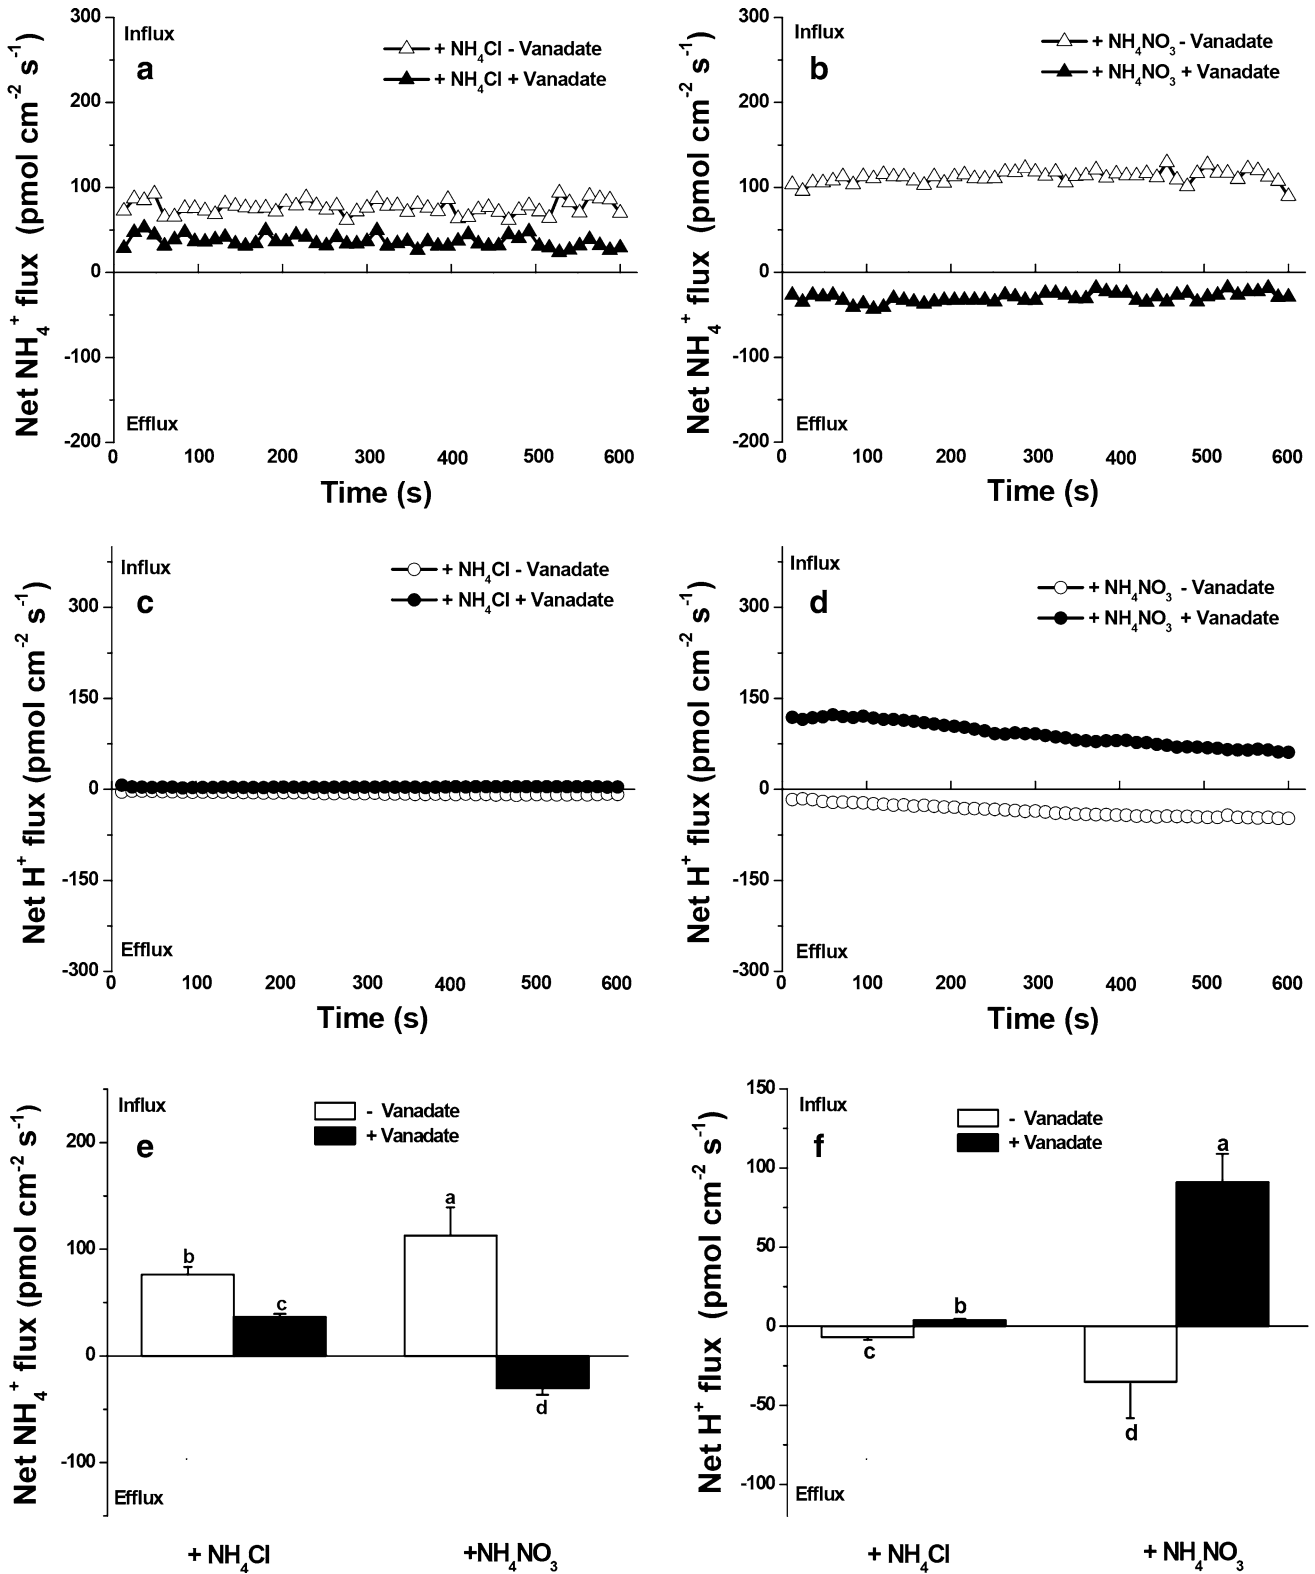

At 15 mm from the root tip of white fine root of *P. popularis* where the maximal net  $\text{NO}_3^-$  uptake was detected, net  $\text{NO}_3^-$  fluxes were investigated for more details (Fig. 4a, b, e). At this point, net  $\text{NO}_3^-$  influxes showed little fluctuation in 10 min (Fig. 4a, b). Under 0.1 mM  $\text{KNO}_3$  conditions, net influx of  $\text{NO}_3^-$  in 10 min was ca. 83.3  $\text{pmol cm}^{-2} \text{ s}^{-1}$  in roots, but a significant decrease (ca. 32 %) was found after exposure to 0.5 mM orthovanadate (Fig. 4e). Under 0 mM orthovanadate conditions, net influx of  $\text{NO}_3^-$  was inhibited by 39 % in roots exposed to 0.1 mM  $\text{NH}_4\text{NO}_3$  compared with that in roots exposed to 0.1 mM  $\text{KNO}_3$  (Fig. 4e). Under 0.1 mM  $\text{NH}_4\text{NO}_3$  conditions, the orthovanadate treatment decreased net influx of  $\text{NO}_3^-$  by 48 % (Fig. 4e).

Along with net  $\text{NO}_3^-$  influx measurement, net  $\text{H}^+$  fluxes were also determined (Fig. 4c, d, f). The mean of net efflux of  $\text{H}^+$  in 10 min was  $-27.8 \text{ pmol cm}^{-2} \text{ s}^{-1}$  in roots exposed to 0.1 mM  $\text{KNO}_3$  and it was markedly reduced by 69 % after the orthovanadate treatment (Fig. 4f). Under 0 mM orthovanadate conditions, net efflux of  $\text{H}^+$  was suppressed by 74 % in roots exposed to 0.1 mM  $\text{NH}_4\text{NO}_3$  compared with that in roots exposed to 0.1 mM  $\text{KNO}_3$  (Fig. 4f). Under 0.1 mM  $\text{NH}_4\text{NO}_3$  conditions, 0.5 mM orthovanadate exposure markedly decreased net  $\text{H}^+$  efflux and displayed net influx of  $\text{H}^+$  compared with 0 mM orthovanadate (Fig. 4f).

The relationships between net  $\text{NO}_3^-$  and  $\text{H}^+$  fluxes were also analyzed for roots in 0.1 mM  $\text{KNO}_3/\text{NH}_4\text{NO}_3$  in the presence or absence of 0.5 mM orthovanadate (Fig. 5a–d). During the monitoring period, net  $\text{H}^+$  effluxes increased with net  $\text{NO}_3^-$  influxes in roots exposed to 0.1 mM  $\text{KNO}_3$ , irrespective of orthovanadate treatments (Fig. 5a, b). Similarly, net  $\text{H}^+$  effluxes increased with net  $\text{NO}_3^-$  influxes in roots exposed to 0.1 mM  $\text{NH}_4\text{NO}_3$  and 0 mM orthovanadate (Fig. 5c), but the relationship turned to that net  $\text{H}^+$  influxes declined with increases in net  $\text{NO}_3^-$  influxes after 0.5 mM orthovanadate exposure (Fig. 5d).

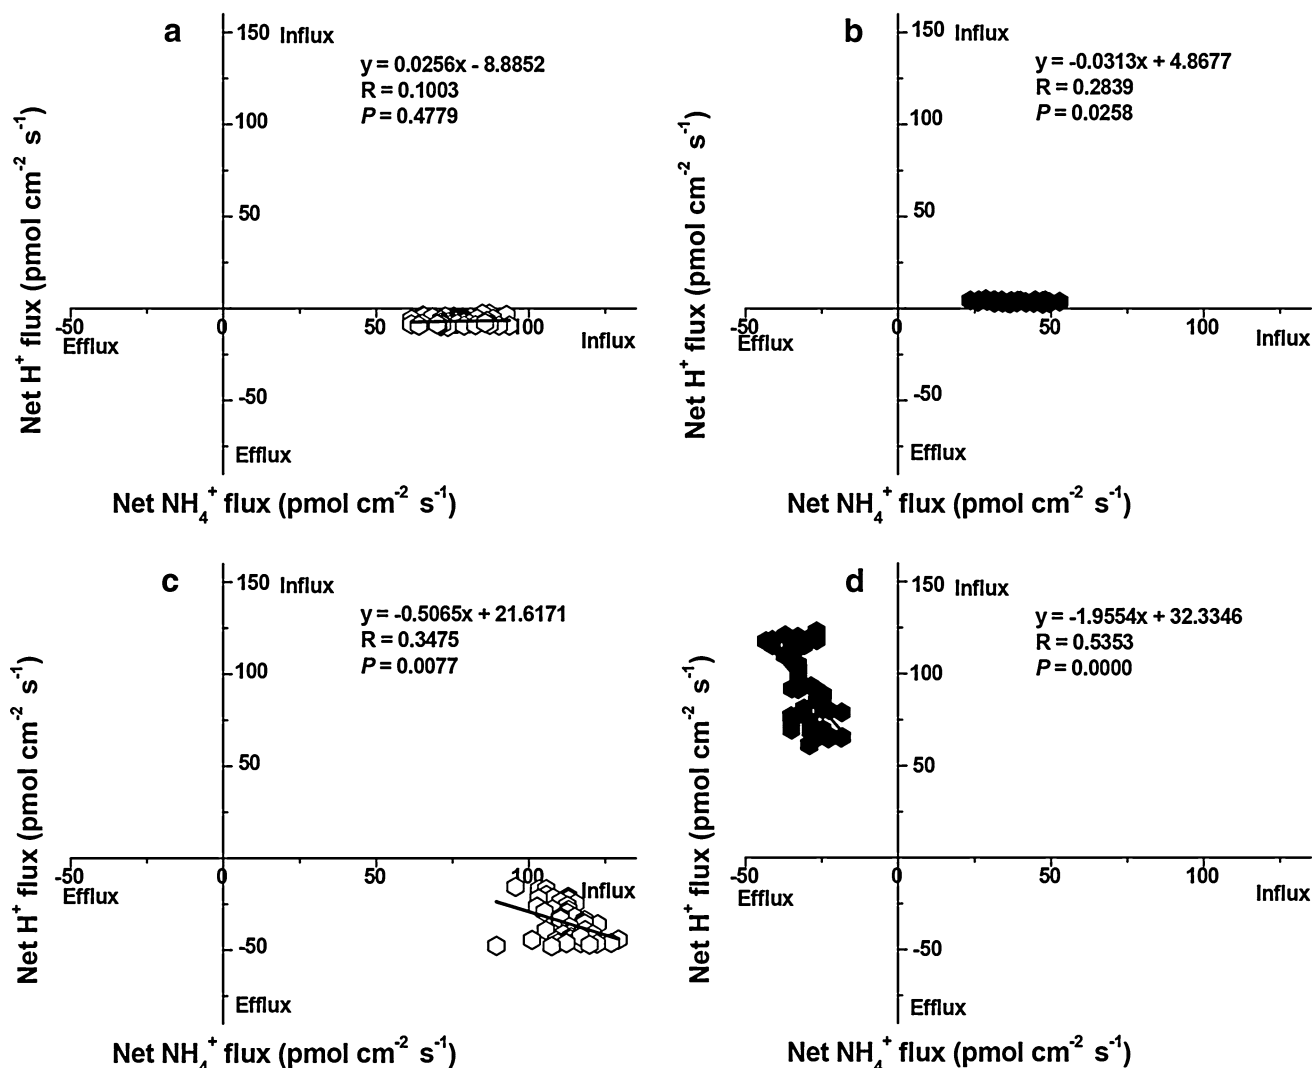

Fluxes of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  in the root xylem

The  $\text{NH}_4^+$  and  $\text{NO}_3^-$  fluxes in the root xylem were monitored using the two-compartment Petri dish system (Fig. 6). Under 0.1 mM  $\text{NH}_4\text{Cl}$  conditions,  $\text{NH}_4^+$  flux was ca.  $-7.6 \text{ nmol cm}^{-2} \text{ s}^{-1}$  in the root xylem, and it

**Fig. 2** Net NH<sub>4</sub><sup>+</sup> (a, b) and H<sup>+</sup> (c, d) fluxes in 10 min at 10 mm from the root tips of fine roots of *P. popularis*. The mean fluxes of NH<sub>4</sub><sup>+</sup> (e) and H<sup>+</sup> (f) within the measuring period are also shown. Data indicate mean ± SE (*n* = 6). The measuring solution (pH 5.5) contained 1 mM KCl and 0.1 mM CaCl<sub>2</sub> besides the following compounds: +NH<sub>4</sub>Cl - Vanadate, 0.1 mM NH<sub>4</sub>Cl and no

vanadate; +NH<sub>4</sub>Cl + Vanadate, 0.1 mM NH<sub>4</sub>Cl and 0.5 mM vanadate; +NH<sub>4</sub>NO<sub>3</sub> - Vanadate, 0.1 mM NH<sub>4</sub>NO<sub>3</sub> and no vanadate; +NH<sub>4</sub>NO<sub>3</sub> + Vanadate, 0.1 mM NH<sub>4</sub>NO<sub>3</sub> and 0.5 mM vanadate. Bars labeled with different letters indicate significant difference between the treatments

**Fig. 3** The relationships between net NH<sub>4</sub><sup>+</sup> fluxes and net H<sup>+</sup> fluxes in fine roots of *P. popularis* exposed to the measuring solution (pH 5.5) contained 1 mM KCl and 0.1 mM CaCl<sub>2</sub> besides the following compounds: +NH<sub>4</sub>Cl – Vanadate, 0.1 mM NH<sub>4</sub>Cl and no vanadate

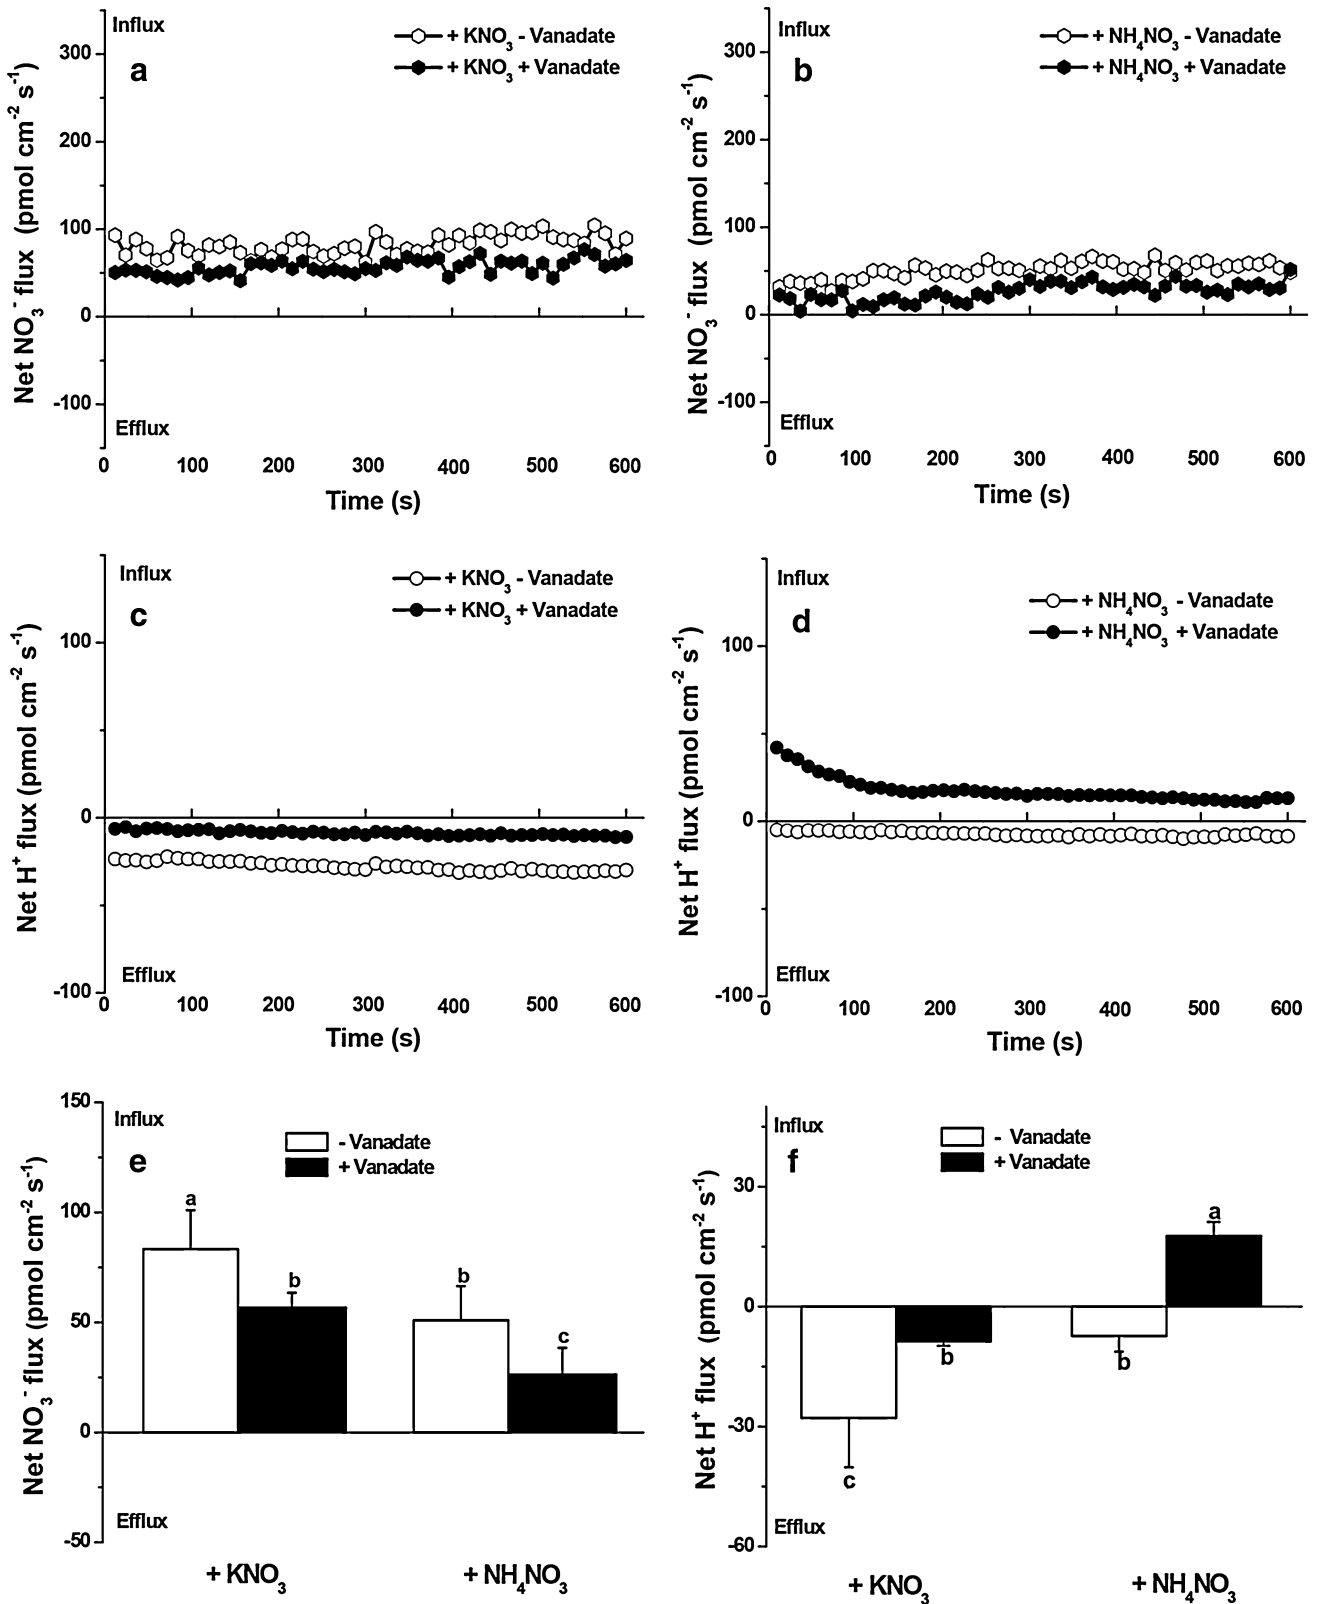

(a); +NH<sub>4</sub>Cl + Vanadate, 0.1 mM NH<sub>4</sub>Cl and 0.5 mM vanadate (b); +NH<sub>4</sub>NO<sub>3</sub> – Vanadate, 0.1 mM NH<sub>4</sub>NO<sub>3</sub> and no vanadate (c); +NH<sub>4</sub>NO<sub>3</sub> + Vanadate, 0.1 mM NH<sub>4</sub>NO<sub>3</sub> and 0.5 mM vanadate (d)

significantly decreased after exposure to 0.5 mM orthovanadate (Fig. 6a). Under 0 mM orthovanadate conditions, NH<sub>4</sub><sup>+</sup> flux tended to reduce in the root xylem exposed to 0.1 mM NH<sub>4</sub>NO<sub>3</sub> compared with that under 0.1 mM NH<sub>4</sub>Cl (Fig. 6a). Under 0.1 mM NH<sub>4</sub>NO<sub>3</sub> conditions, the orthovanadate treatment decreased NH<sub>4</sub><sup>+</sup> flux in the root xylem by 77 % (Fig. 6a). Under 0.1 mM KNO<sub>3</sub> conditions, NO<sub>3</sub><sup>-</sup> flux was ca.  $-3.2 \text{ nmol cm}^{-2} \text{ s}^{-1}$  in the root xylem, and it tended to decrease after exposure to 0.5 mM orthovanadate (Fig. 6b). Under 0 mM orthovanadate conditions, NO<sub>3</sub><sup>-</sup> flux tended to decline in the root xylem exposed to 0.1 mM NH<sub>4</sub>NO<sub>3</sub> compared with that under 0.1 mM KNO<sub>3</sub> (Fig. 6b). Under 0.1 mM NH<sub>4</sub>NO<sub>3</sub> conditions, the orthovanadate treatment decreased NO<sub>3</sub><sup>-</sup> flux in the root xylem by 75 % (Fig. 6b).

## Discussion

### Spatial variability of net NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup> fluxes along the root tip of *P. popularis*

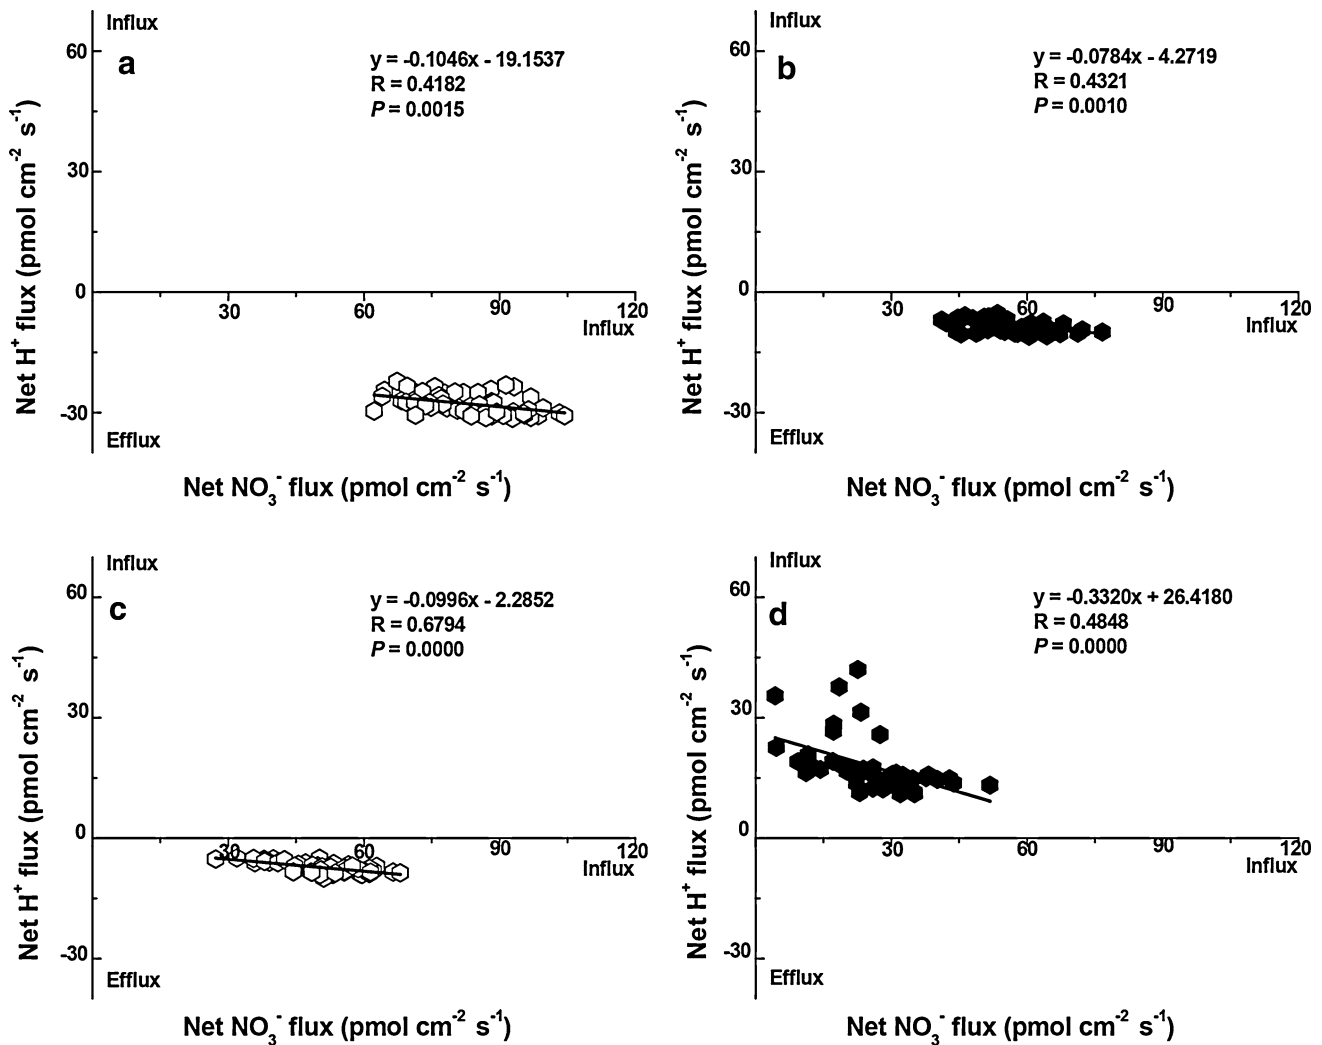

The apical region of the root is characterized by root cap, meristematic, elongation and maturation zones, which have distinct anatomical and functional features leading to different abilities to absorb nutrient ions (Enstone et al. 2001; Fang et al. 2007; Li et al. 2010). Previous studies suggest that different zones of root apical region have distinct net fluxes of NH<sub>4</sub><sup>+</sup> and/or NO<sub>3</sub><sup>-</sup> (Fang et al. 2007; Li et al. 2010). The observation that spatial variability and net influxes of NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup> were the largest at 10 and 15 mm, respectively, from the root tips in fine roots of

**Fig. 4** Net NO<sub>3</sub><sup>-</sup> (a, b) and H<sup>+</sup> (c, d) fluxes in 10 min at 15 mm from the root tips of fine roots of *P. popularis*. The mean net influxes of NO<sub>3</sub><sup>-</sup> (e) and H<sup>+</sup> (f) within the measuring period are also shown. Data indicate mean ± SE (*n* = 6). The measuring solution (pH 5.5) contained 1 mM KCl and 0.1 mM CaCl<sub>2</sub> besides the following compounds: +KNO<sub>3</sub> -

Vanadate, 0.1 mM KNO<sub>3</sub> and no vanadate; +KNO<sub>3</sub> + Vanadate, 0.1 mM KNO<sub>3</sub> and 0.5 mM vanadate; +NH<sub>4</sub>NO<sub>3</sub> - Vanadate, 0.1 mM NH<sub>4</sub>NO<sub>3</sub> and no vanadate; +NH<sub>4</sub>NO<sub>3</sub> + Vanadate, 0.1 mM NH<sub>4</sub>NO<sub>3</sub> and 0.5 mM vanadate. Bars labeled with different letters indicate significant difference between the treatments

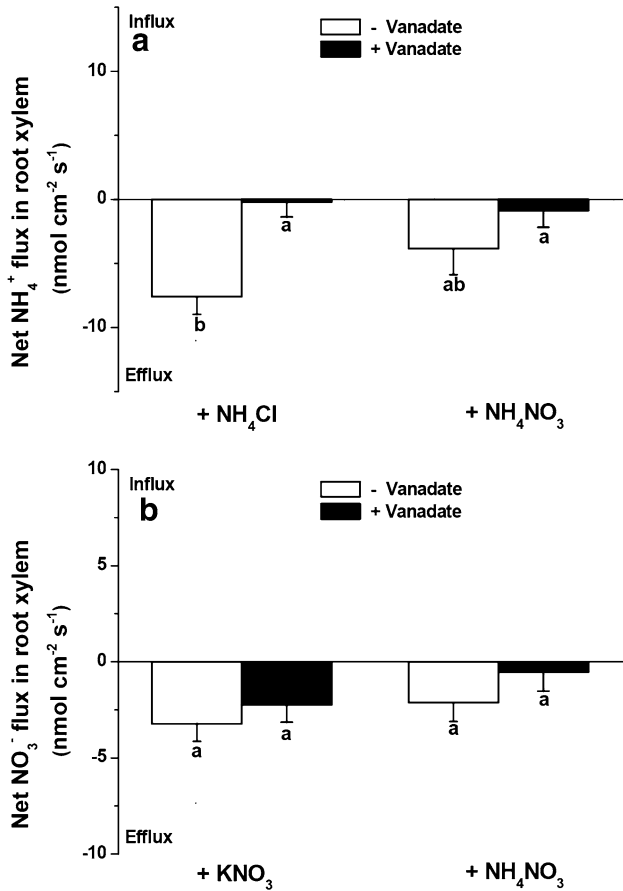

**Fig. 5** The relationships between net  $\text{NO}_3^-$  influxes and net  $\text{H}^+$  fluxes in fine roots of *P. popularis* exposed to the measuring solution (pH 5.5) contained 1 mM KCl and 0.1 mM  $\text{CaCl}_2$  besides the following compounds: + $\text{KNO}_3$  – Vanadate, 0.1 mM  $\text{KNO}_3$  and no

vanadate (a); + $\text{KNO}_3$  + Vanadate, 0.1 mM  $\text{KNO}_3$  and 0.5 mM vanadate (b); + $\text{NH}_4\text{NO}_3$  – Vanadate, 0.1 mM  $\text{NH}_4\text{NO}_3$  and no vanadate (c); + $\text{NH}_4\text{NO}_3$  + Vanadate, 0.1 mM  $\text{NH}_4\text{NO}_3$  and 0.5 mM vanadate (d)

*P. popularis* (Fig. 1b, c) is consistent with the results of previous studies in woody plants. Net fluxes of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  are the largest at 5–20 and 0–30 mm from the root tips in Douglas fir and at 5 and 0–10 mm from the root tips in lodgepole pine, respectively (Hawkins et al. 2008; Hawkins and Robbins 2010). In *Picea abies*, the maximal uptake rates of  $\text{NO}_3^-$  occur at 0–10 mm from the root tips and the  $\text{NO}_3^-$  fluxes behind 10 mm from the root tips are significantly decreased (Boukcim and Plassard 2003). Taken together, these results suggest that spatial variation in uptake of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  may be linked with different anatomical properties along the root and the root tip is of key importance for uptake of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  in roots of woody plants.

Net  $\text{NH}_4^+$  and  $\text{NO}_3^-$  fluxes associated with PM  $\text{H}^+$ -ATPases and the interaction of both ions

Net fluxes of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  in plant roots are determined by the sum of influx and efflux of the respective ion. Net fluxes of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  reflect the results of N assimilation and uptake kinetics of these ions into root cells (Britto and Kronzucker 2006; Hawkins et al. 2008). The high net uptake of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  in fine roots of *P. popularis* (Figs. 2, 4) suggests that cytosolic concentrations of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  are lower than the thresholds which need to be maintained for N assimilation to support growth. As fast-growing species, poplars have strong demands for N (Luo et al. 2008; Rennenberg et al. 2010; Li

**Fig. 6** Net fluxes of NH<sub>4</sub><sup>+</sup> (a) and NO<sub>3</sub><sup>-</sup> (b) from xylem of fine roots of *P. popularis*. Data indicate mean ± SE (n = 10). The measuring solution (pH 5.5) contained 1 mM KCl and 0.1 mM CaCl<sub>2</sub> besides the following compounds: +NH<sub>4</sub>Cl - Vanadate, 0.1 mM NH<sub>4</sub>Cl and no vanadate; +NH<sub>4</sub>Cl + Vanadate, 0.1 mM NH<sub>4</sub>Cl and 0.5 mM vanadate; +NH<sub>4</sub>NO<sub>3</sub> - Vanadate, 0.1 mM NH<sub>4</sub>NO<sub>3</sub> and no vanadate; +NH<sub>4</sub>NO<sub>3</sub> + Vanadate, 0.1 mM NH<sub>4</sub>NO<sub>3</sub> and 0.5 mM vanadate; +KNO<sub>3</sub> - Vanadate, 0.1 mM KNO<sub>3</sub> and no vanadate; +KNO<sub>3</sub> + Vanadate, 0.1 mM KNO<sub>3</sub> and 0.5 mM vanadate. Bars labeled with different letters indicate significant difference between the treatments

et al. 2012). The poplar plants used here were cultivated with low NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup> in the nutrient solution. Therefore, strong net uptake of NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup> in fine roots of *P. popularis* was expected to occur when NH<sub>4</sub><sup>+</sup> or NO<sub>3</sub><sup>-</sup> alone or together were present in the measuring solution.

The net uptake of NH<sub>4</sub><sup>+</sup> which ranged from 76 to 113 pmol cm<sup>-2</sup> s<sup>-1</sup> and of NO<sub>3</sub><sup>-</sup> from 51 to 83 pmol cm<sup>-2</sup> s<sup>-1</sup> in fine roots of *P. popularis* (Figs. 2e, 4e) is relatively larger in comparison with those found in roots of other woody plants measured under similar conditions. For example, net NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup> uptake of ca. 40–80 and 28 nmol m<sup>-2</sup> s<sup>-1</sup> (i.e., 4–8 and 2.8 pmol cm<sup>-2</sup> s<sup>-1</sup>), respectively, was reported for tap roots of *Eucalyptus nitens* in 0.1 mM NH<sub>4</sub><sup>+</sup> or NO<sub>3</sub><sup>-</sup> solutions at pH 6.1 (Garnett et al. 2001, 2003). The net NH<sub>4</sub><sup>+</sup> and

NO<sub>3</sub><sup>-</sup> uptake of seedlings of Douglas fir and lodgepole pine is ca. 8–11 and 11–19 nmol m<sup>-2</sup> s<sup>-1</sup> (i.e., 0.8–1.1 and 1.1–1.9 pmol cm<sup>-2</sup> s<sup>-1</sup>), respectively, in primary roots in solutions with 0.05 mM NH<sub>4</sub><sup>+</sup> or NO<sub>3</sub><sup>-</sup> (Hawkins et al. 2008). N-starvation pretreatment had also been applied to the coniferous seedlings (Hawkins et al. 2008). Although fine roots derived from cuttings of *P. popularis* may be different from tap roots of seed-derived *E. nitens* and coniferous species, the higher net uptake of NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup> in fine roots of *P. popularis* underlines that poplar seedlings need higher uptake rates of NH<sub>4</sub><sup>+</sup> and/or NO<sub>3</sub><sup>-</sup> to meet N demands for fast growth.

NO<sub>3</sub><sup>-</sup> is co-transported with H<sup>+</sup> through a symporter into root cells, whereas NH<sub>4</sub><sup>+</sup> is transported via a uniporter and/or a symporter (co-transport with H<sup>+</sup>) to the cytosol (Garnett et al. 2003; Britto and Kronzucker 2006; Miller et al. 2009). Thus, inactivation of PM H<sup>+</sup>-ATPases may inhibit uptake of NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup> in plant roots because the proton motive force is blocked (Santi et al. 1995, 2003; Sorgona et al. 2010, 2011). In line with this presumption, application of a specific inhibitor for PM H<sup>+</sup>-ATPases caused a significant decline in net uptake of NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup> or even resulted in net effluxes of NH<sub>4</sub><sup>+</sup> from poplar roots (Figs. 2e, 4e). These results demonstrate that PM H<sup>+</sup>-ATPases play a critical role in uptake of NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup> in roots of *P. popularis*.

Uptake rates of NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup> in plant roots are affected by the presence or absence of both ions together in solutions. In this study, net NH<sub>4</sub><sup>+</sup> uptake was strongly stimulated in the presence of NO<sub>3</sub><sup>-</sup>, whereas net NO<sub>3</sub><sup>-</sup> uptake was inhibited by the presence of NH<sub>4</sub><sup>+</sup> under no vanadate exposure conditions (Figs. 2e, 4e). The induced effect of NO<sub>3</sub><sup>-</sup> on net NH<sub>4</sub><sup>+</sup> uptake in poplar roots can be the results of induction of NH<sub>4</sub><sup>+</sup> uptake, suppression of NH<sub>4</sub><sup>+</sup> release or both processes. The induced effects of NO<sub>3</sub><sup>-</sup> on net NH<sub>4</sub><sup>+</sup> uptake have been also observed in previous studies (Kronzucker et al. 1999b; Babourina et al. 2007). The synergistic effect of NO<sub>3</sub><sup>-</sup> on net NH<sub>4</sub><sup>+</sup> uptake in poplar roots might be associated with higher activity of NH<sub>4</sub><sup>+</sup> transporters involved in homeostasis of cytosolic NH<sub>4</sub><sup>+</sup> (by a higher rate of NH<sub>4</sub><sup>+</sup> transfer into vacuole and/or plastids or further to the xylem) or with a more complicated feedback response via metabolism such as the increased activities of NH<sub>4</sub><sup>+</sup> assimilation enzymes (Babourina et al. 2007). All these processes may lead to a lower cytoplasmic NH<sub>4</sub><sup>+</sup> concentration in root cells, facilitating a higher NH<sub>4</sub><sup>+</sup> uptake from and/or a lower NH<sub>4</sub><sup>+</sup> release to the apoplast. However, net NH<sub>4</sub><sup>+</sup> flux in the xylem of fine roots of *P. popularis* tended to decrease in the presence of NO<sub>3</sub><sup>-</sup> under no vanadate conditions (Fig. 6a), indicating that the synergistic effect of NO<sub>3</sub><sup>-</sup> on net NH<sub>4</sub><sup>+</sup> uptake in poplar root surface may be mainly due to a higher rate of NH<sub>4</sub><sup>+</sup> transfer into vacuoles and/or plastids. The switch of

net  $\text{NH}_4^+$  uptake to net release in the presence of  $\text{NO}_3^-$  in poplar roots after vanadate exposure (Fig. 2e) indicates that provision of  $\text{NO}_3^-$  probably stimulates the activity of  $\text{NH}_4^+$  efflux systems under this condition. Since  $\text{NO}_3^-$  can act as a signal molecule in root tips (Walch-Liu and Forde 2008; Forde and Walch-Liu 2009), it may function as a messenger to activate  $\text{NH}_4^+$  efflux systems in poplar roots. Although specific transporters for  $\text{NH}_4^+$  efflux are unidentified yet,  $\text{NH}_4^+$  efflux, e.g., via ammonium transporters, non-selective cation channels and  $\text{NH}_4^+/\text{H}^+$  antiporters, is a critical step in the futile  $\text{NH}_4^+$  cycling in root cells when  $\text{NH}_4^+$  is present in excess (Britto et al. 2001; Loque and von Wiren 2004; Britto and Kronzucker 2006).

Although there exist inconsistent results about influence of  $\text{NH}_4^+$  co-provision on net  $\text{NO}_3^-$  uptake in roots of woody plants (e.g., Garnett et al. 2003; Hawkins et al. 2008), most studies suggest that the presence of  $\text{NH}_4^+$  in growth media may reduce net  $\text{NO}_3^-$  uptake as the result of decreased  $\text{NO}_3^-$  uptake, elevated  $\text{NO}_3^-$  release or both processes in roots of woody plants (Kronzucker et al. 1999a; Garnett et al. 2003; Gobert and Plassard 2007). Our results about decreases in net  $\text{NO}_3^-$  uptake by  $\text{NH}_4^+$  co-provision in poplar roots (Fig. 4e) are in good agreement with those of previous studies. It is suggested that the increases in  $\text{NH}_4^+$  in root cells are related to the decreases in gene expression of  $\text{NO}_3^-$  transporters involved in high-affinity transport process (Zhuo et al. 1999; Vidmar et al. 2000), which may lead to lower activity of  $\text{NO}_3^-$  transporters and to reduce  $\text{NO}_3^-$  uptake. This negative regulation process may be induced by  $\text{NH}_4^+$  in poplar roots exposed to  $\text{NH}_4\text{NO}_3$ . Inhibition of  $\text{NO}_3^-$  influx and/or activation of  $\text{NO}_3^-$  efflux system such as aquaporins may also be involved (Ikeda et al. 2002). Since a significant amount of absorbed  $\text{NO}_3^-$  is loaded to the xylem in poplar roots (Min et al. 1998), the tendency to reduce  $\text{NO}_3^-$  flux to the xylem in fine roots of *P. popularis* (Fig. 6b) may also contribute to the lower net  $\text{NO}_3^-$  uptake in the presence of  $\text{NH}_4^+$  in the measuring solution. Furthermore, since  $\text{NO}_3^-$  enters root cells via a symporter with  $\text{H}^+$ , inhibition effect of  $\text{NH}_4^+$  on net  $\text{H}^+$  release (Fig. 4f) may also lead to decreased  $\text{H}^+$  availability for  $\text{NO}_3^-$  co-transport in poplar roots.

#### $\text{H}^+$ fluxes and correlations between net $\text{NH}_4^+$ or $\text{NO}_3^-$ fluxes and net $\text{H}^+$ fluxes

Protons play a pivotal role in plant uptake of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  because the  $\text{H}^+$  gradient maintained by PM  $\text{H}^+$ -ATPases facilitates absorption of these nutrient ions (Miller and Cramer 2004; Britto and Kronzucker 2006). Net  $\text{H}^+$  effluxes are often observed during  $\text{NH}_4^+$  and  $\text{NO}_3^-$  absorption in roots of woody plants (e.g., Hawkins et al. 2008; Hawkins and Robbins 2010). Consistently, net  $\text{H}^+$  release was observed in poplar roots exposed to  $\text{NH}_4^+$ ,

$\text{NO}_3^-$  or both ions containing solutions under 0 mM vanadate condition (Figs. 2f, 4f). Net  $\text{H}^+$  efflux may be associated with uptake and/or assimilation of  $\text{NH}_4^+$  or  $\text{NO}_3^-$  in fine roots of *P. popularis*. There is evidence that  $\text{H}^+$  may be cotransported with cations such as  $\text{NH}_4^+$  (Wang et al. 1994) or with anions such as  $\text{NO}_3^-$  through transporters (Marschner 2002; Hawkins and Robbins 2010). Additionally, roots of many species exhibit net  $\text{H}^+$  efflux in apical regions to maintain the acid environment for cell wall expansion (Bloom et al. 2003). Since PM  $\text{H}^+$ -ATPases are inactivated under vanadate exposure, maintaining net  $\text{H}^+$  fluxes in  $\text{NH}_4^+$ ,  $\text{NO}_3^-$  or both ions containing solutions in poplar roots during the monitoring period are probably due to (1) the futile cycling of  $\text{NH}_4^+/\text{NO}_3^-$  via channels of these ions across root cell PM (Britto et al. 2001; Britto and Kronzucker 2003, 2006) and/or (2) loading cytoplasmic and vacuolar pools, assimilation and transport to xylem of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  in root cells (Garnett et al. 2003). In fact, our data showed that transport of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  to root xylem still occurred in root cells of *P. popularis* after vanadate exposure, although these ion fluxes to root xylem remained small (Fig. 6).

The correlation is expected between net  $\text{H}^+$  flux and net  $\text{NH}_4^+/\text{NO}_3^-$  flux since  $\text{H}^+$  is tightly associated with  $\text{NH}_4^+$  or  $\text{NO}_3^-$  during the uptake and assimilation processes in plant roots under 0 mM vanadate conditions. Our data are consistent with this anticipation except that no correlation was found between net  $\text{H}^+$  flux and net  $\text{NH}_4^+$  flux in fine roots of *P. popularis* under 0.1 mM  $\text{NH}_4\text{Cl}$  and 0 mM vanadate condition (Figs. 3a, c, 5a, c). The correlations between net  $\text{H}^+$  fluxes and net  $\text{NH}_4^+/\text{NO}_3^-$  fluxes have also been reported in roots of Douglas-fir, lodgepole pine and *Eucalyptus nitens* (Garnett et al. 2001; Hawkins et al. 2008). Moreover, the ratio between net  $\text{H}^+$  flux and net  $\text{NH}_4^+$  flux is reported to be  $-1.6$  (efflux) to 1 (influx) and the flux stoichiometry for  $\text{H}^+$  to  $\text{NO}_3^-$  is  $-0.8$  (efflux) to 1 (influx) in roots of *E. nitens* (Garnett et al. 2003). In contrast to these stoichiometric relations in *E. nitens*, the ratios between net  $\text{H}^+$  effluxes and net  $\text{NH}_4^+$  or  $\text{NO}_3^-$  influxes were much smaller in fine roots of *P. popularis* (Figs. 3a, c, 5a, c). Although no correlation existed between net  $\text{H}^+$  flux and net  $\text{NH}_4^+$  flux in fine roots of *P. popularis* under 0.1 mM  $\text{NH}_4\text{Cl}$  and 0 mM vanadate condition (Fig. 3a), a significant correlation was detected after vanadate exposure (Fig. 3b). Similarly, the correlation between net  $\text{H}^+$  fluxes and net  $\text{NH}_4^+$  fluxes also markedly changed under 0.1 mM  $\text{NH}_4\text{NO}_3$  after vanadate treatment (Fig. 3c, d). In the same line, the correlation between net  $\text{H}^+$  fluxes and net  $\text{NO}_3^-$  fluxes altered under 0.1 mM  $\text{NH}_4\text{NO}_3$  after vanadate exposure (Fig. 5c, d). Changes in these correlations may be largely due to the vanadate treatment which inactivates PM  $\text{H}^+$ -ATPases resulting in significant reductions in  $\text{H}^+$  effluxes from root cells. In previous

studies, to our knowledge, no vanadate treatment is reported to link the correlations between net  $H^+$  fluxes and net  $NH_4^+$  or  $NO_3^-$  fluxes. Thus, it is the first time for us to demonstrate changes in correlations between net  $H^+$  fluxes and net  $NH_4^+$  or  $NO_3^-$  fluxes after inactivation of PM  $H^+$ -ATPases, highlighting the tight coupling between net  $H^+$  fluxes and net  $NH_4^+$  or  $NO_3^-$  fluxes. Although the stoichiometric correlations have been explored between net  $H^+$  fluxes and net  $NH_4^+$  or  $NO_3^-$  fluxes in previous studies, the biological meaning underlying these stoichiometric relations remains unclear (Newman 2001; Garnett et al. 2003; Fang et al. 2007). Since the SIET method used in this study just measures net fluxes of  $NH_4^+/NO_3^-/H^+$ , not the individual influx/efflux of these ions in the measuring solutions, in combination with possible confounding effects of N assimilation ( $H^+$ -consuming and -producing processes involved), it is a challenge to explain the biological meaning of stoichiometric relations between net  $H^+$  fluxes and net  $NH_4^+$  or  $NO_3^-$  fluxes based on the correlations in fine roots of *P. popularis* (Newman 2001; Garnett et al. 2003; Fang et al. 2007).
